(Received 2 May 2014; accepted 26 August 2014; published online 18 September 2014)

Perovskite-containing solar cells were fabricated in a two-step procedure in which  $\text{PbI}_2$  is deposited via spin-coating and subsequently converted to the  $\text{CH}_3\text{NH}_3\text{PbI}_3$  perovskite by dipping in a solution of  $\text{CH}_3\text{NH}_3\text{I}$ . By varying the dipping time from 5 s to 2 h, we observe that the device performance shows an unexpectedly remarkable trend. At dipping times below 15 min the current density and voltage of the device are enhanced from 10.1  $\text{mA}/\text{cm}^2$  and 933 mV (5 s) to 15.1  $\text{mA}/\text{cm}^2$  and 1036 mV (15 min). However, upon further conversion, the current density decreases to 9.7  $\text{mA}/\text{cm}^2$  and 846 mV after 2 h. Based on X-ray diffraction data, we determined that remnant  $\text{PbI}_2$  is always present in these devices. Work function and dark current measurements showed that the remnant  $\text{PbI}_2$  has a beneficial effect and acts as a blocking layer between the  $\text{TiO}_2$  semiconductor and the perovskite itself reducing the probability of back electron transfer (charge recombination). Furthermore, we find that increased dipping time leads to an increase in the size of perovskite crystals at the perovskite-hole-transporting material interface. Overall, approximately 15 min dipping time ( $\sim 2\%$  unconverted  $\text{PbI}_2$ ) is necessary for achieving optimal device efficiency. © 2014 Author(s). With the global growth in energy demand and with compelling climate-related environmental concerns, alternatives to the use of non-renewable and noxious fossil fuels are needed.<sup>1</sup> One such alternative energy resource, and arguably the only legitimate long-term solution, is solar energy. Photovoltaic devices which are capable of converting the photon flux to electricity are one such device.<sup>2</sup> Over the last 2 years, halide hybrid perovskite-based solar cells with high efficiency have engendered enormous interest in the photovoltaic community.<sup>3,4</sup> Among the perovskite choices, methylammonium lead iodide ( $\text{MAPbI}_3$ ) has become the archetypal light absorber. Recently, however, Sn-based perovskites have been successfully implemented in functional solar cells.<sup>5,6</sup>  $\text{MAPbI}_3$  is an attractive light absorber due to its extraordinary absorption coefficient of  $1.5 \times 10^4 \text{ cm}^{-1}$  at 550 nm;<sup>7</sup> it would take roughly 1  $\mu\text{m}$  of material to absorb 99% of the flux at 550 nm. Furthermore, with a band gap of 1.55 eV (800 nm), assuming an external quantum efficiency of 90%, a maximum current density of ca. 23  $\text{mA}/\text{cm}^2$  is attainable with  $\text{MAPbI}_3$ .

Recent reports have commented on the variability in device performance as a function of perovskite layer fabrication.<sup>8</sup> In our laboratory, we too have observed that seemingly identical films

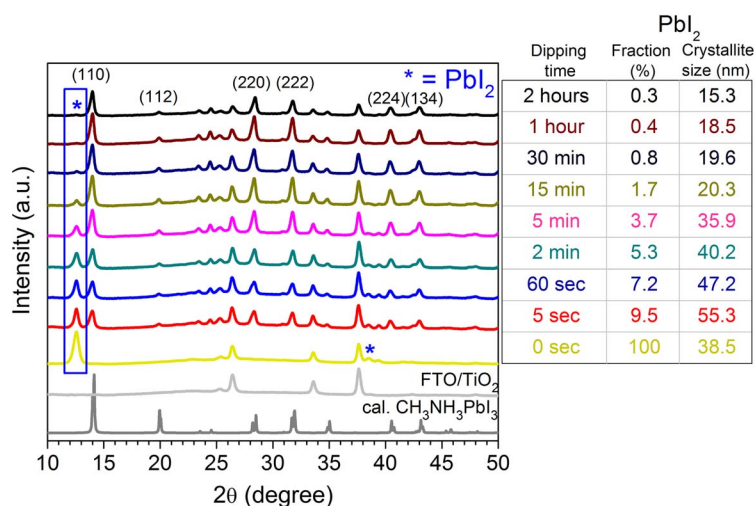

FIG. 1. X-ray diffraction patterns of  $\text{CH}_3\text{NH}_3\text{PbI}_3$  films with increasing dipping time (% composition of  $\text{PbI}_2$  was determined by Rietveld analysis (see Sec. S3 of the supplementary material for the Rietveld analysis details).

have markedly different device performance. For example, when our films of  $\text{PbI}_2$  are exposed to MAI for several seconds (ca. 60 s), then a light brown colored film is obtained rather than the black color commonly observed for bulk  $\text{MAPbI}_3$  (see Sec. S2 of the supplementary material for the optical band gap of bulk  $\text{MAPbI}_3$ ).<sup>23</sup> This brown color suggests only partial conversion to  $\text{MAPbI}_3$  and yields solar cells exhibiting a  $J_{\text{sc}}$  of 13.4  $\text{mA}/\text{cm}^2$  and a  $V_{\text{oc}}$  of 960 mV; these values are significantly below the 21.3  $\text{mA}/\text{cm}^2$  and 1000 mV obtained by others.<sup>4</sup> Under the hypothesis that fully converted films will achieve optimal light harvesting efficiency, we increased the conversion time from seconds to 2 h. Unexpectedly, the 2-h dipping device did not show an improved photovoltaic response ( $J_{\text{sc}} = 9.7 \text{ mA}/\text{cm}^2$ ,  $V_{\text{oc}} = 846 \text{ mV}$ ) even though conversion to  $\text{MAPbI}_3$  appeared to be complete. With the only obvious difference between these two devices being the dipping time, we hypothesized that the degree of conversion of  $\text{PbI}_2$  to the  $\text{MAPbI}_3$  perovskite is an important parameter in obtaining optimal device performance. We thus set out to understand the correlation between the method of fabrication of the  $\text{MAPbI}_3$  layer, the precise chemical compositions, and both the physical and photo-physical properties of the film. We report here that remnant  $\text{PbI}_2$  is crucial in forming a barrier layer to electron interception/recombination leading to optimized  $J_{\text{sc}}$  and  $V_{\text{oc}}$  in these hybrid perovskite-based solar cells.

We constructed perovskite-containing devices using a two-step deposition method according to a reported procedure with some modifications.<sup>4</sup> (see Sec. S1 of the supplementary material for the experimental details).<sup>23</sup>  $\text{MAPbI}_3$ -containing photo-anodes were made by varying the dipping time of the  $\text{PbI}_2$ -coated photo-anode in MAI solution. In order to minimize the effects from unforeseen variables, care was taken to ensure that all films were prepared in an identical manner. The compositions of final  $\text{MAPbI}_3$ -containing films were monitored by X-ray diffraction (XRD). Independently of the dipping times, only the  $\beta$ -phase of the  $\text{MAPbI}_3$  is formed (Figure 1).<sup>9</sup> However, in addition to the  $\beta$ -phase, all films also showed the presence of unconverted  $\text{PbI}_2$  (Figure 1, marked with \*) which can be most easily observed via the (001) and (003) reflections at  $2\theta = 12.56^\circ$  and  $38.54^\circ$  respectively. As the dipping time is increased, the intensities of  $\text{PbI}_2$  reflections decrease with a concomitant increase in the  $\text{MAPbI}_3$  intensities. In addition to the decrease in peak intensities of  $\text{PbI}_2$ , the peak width increases as the dipping time increases indicating that the size of the  $\text{PbI}_2$  crystallites is decreasing, as expected, and the converse is observed for the  $\text{MAPbI}_3$  reflections. This observation suggests that the conversion process begins from the surface of the  $\text{PbI}_2$  crystallites and proceeds toward the center where the crystallite domain size of the  $\text{MAPbI}_3$  phase increases and that of  $\text{PbI}_2$  diminishes. Interestingly, the remnant  $\text{PbI}_2$  phase can be seen in the data of other reports, but has not been identified as a primary source of variability in cell performance.<sup>8,10</sup>

Considering that the perovskite is the primary light absorber within the device, we wanted to further investigate how the optical absorption of the film changes with increasing dipping time

FIG. 2. Absorption spectra of  $\text{CH}_3\text{NH}_3\text{PbI}_3$  films as a function of unconverted  $\text{PbI}_2$  phase fraction.FIG. 3. (a) J-V curves and (b) EQE of  $\text{CH}_3\text{NH}_3\text{PbI}_3$ -based devices as a function of unconverted  $\text{PbI}_2$  phase fraction.

(Figure 2).<sup>11,12</sup> The pure  $\text{PbI}_2$  film shows a band gap of 2.40 eV, consistent with the yellow color of  $\text{PbI}_2$ . As the  $\text{PbI}_2$  film is gradually converted to the perovskite, the band gap is progressively shifted toward 1.60 eV. The deviation of  $\text{MAPbI}_3$ 's band gap (1.60 eV) from that of the bulk  $\text{MAPbI}_3$  material (1.55 eV) could be explained by quantum confinement effects related with the sizes of  $\text{TiO}_2$  and  $\text{MAPbI}_3$  crystallites and their interfacial interaction.<sup>13,14</sup> Interestingly, we also noticed the presence of a second absorption in the light absorber layer, in which the gap gradually red shifts from 1.90 eV to 1.50 eV as the  $\text{PbI}_2$  concentration is decreased from 9.5% to 0.3% (Figure 2—blue arrow).

Having established the chemical compositions and optical properties of the light absorber films, we proceeded to examine the photo-physical responses of the corresponding functional devices in order to determine how the remnant  $\text{PbI}_2$  affects device performance. The pure  $\text{PbI}_2$  based device remarkably achieved a 0.4% efficiency with a  $J_{\text{sc}}$  of 2.1  $\text{mA}/\text{cm}^2$  and a  $V_{\text{oc}}$  of 564 mV (Figure 3(a)). Upon progressive conversion of the  $\text{PbI}_2$  layer to  $\text{MAPbI}_3$ , we observe two different regions (Figure 4, Table I). In the first region, the expected behavior is observed; as more  $\text{PbI}_2$  is converted to  $\text{MAPbI}_3$ , the trend is toward higher photovoltaic efficiency, due both to  $J_{\text{sc}}$  and  $V_{\text{oc}}$ , until 1.7%  $\text{PbI}_2$  is reached. The increase in  $J_{\text{sc}}$  is attributable, at least in part, to increasing absorption of light by the perovskite. We speculate that progressive elimination of  $\text{PbI}_2$ , present as a layer between  $\text{TiO}_2$  and the perovskite, also leads to higher net yields for electron injection into  $\text{TiO}_2$  and therefore, higher J values. For a sufficiently thick  $\text{PbI}_2$  spacer layer, electron injection would occur in stepwise fashion, i.e., perovskite  $\rightarrow \text{PbI}_2 \rightarrow \text{TiO}_2$ . Finally, the photovoltage increase is attributable to

<sup>a</sup>Determined from the Rietveld analysis of X-ray diffraction data.

the positive shift in TiO<sub>2</sub>'s quasi-Fermi level as the population of photo-injected electrons is higher with increased concentration of MAPbI<sub>3</sub>.

The second region yields a notably different trend; surprisingly, below a concentration of 2% PbI<sub>2</sub>, J<sub>sc</sub>, V<sub>oc</sub>, and ultimately  $\eta$  decrease. Considering that the light-harvesting efficiency would increase when the remaining 2% PbI<sub>2</sub> is converted to MAPbI<sub>3</sub> (albeit to only a small degree), then the remnant PbI<sub>2</sub> must have some other role. We posit that remnant PbI<sub>2</sub> serves to inhibit detrimental electron-transfer processes (Figure 5). Two such processes are back electron transfer from TiO<sub>2</sub> to holes in the valence band of the perovskite (charge-recombination) or to the holes in the HOMO of the HTM (charge-interception). This retardation of electron interception/recombination observation is reminiscent of the behavior of atomic layer deposited Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> layers that have been employed in dye-sensitized solar cells.<sup>15–18</sup>

It is conceivable that the conversion of PbI<sub>2</sub> to MAPbI<sub>3</sub> occurs from the solution interface toward the TiO<sub>2</sub>/PbI<sub>2</sub> interface and thus would leave sandwiched between TiO<sub>2</sub> and MAPbI<sub>3</sub> a blocking layer of PbI<sub>2</sub> that inhibits charge-interception/recombination. For this hypothesis to be correct, it is crucial that the conduction-band-edge energy (E<sub>cb</sub>) of the PbI<sub>2</sub> be higher than the E<sub>cb</sub> of the TiO<sub>2</sub>.<sup>19–21</sup> The work function of PbI<sub>2</sub> was measured by ultraviolet photoelectron spectroscopy (UPS) and was observed to be at 6.35 eV vs. vacuum level, which is 0.9 eV lower than the valence-band-edge energy (E<sub>vb</sub>) of MAPbI<sub>3</sub> (see Sec. S7 of the supplementary material<sup>23</sup> for the work function of PbI<sub>2</sub>); the E<sub>cb</sub> (4.05 eV) was calculated by subtracting the work function from the band gap (2.30 eV).

FIG. 5. Model of charge-interception/recombination retardation by the unconverted  $\text{PbI}_2$  layer in  $\text{CH}_3\text{NH}_3\text{PbI}_3$ -based solar cell.

FIG. 6. Dark current of  $\text{CH}_3\text{NH}_3\text{PbI}_3$ -based devices as a function of unconverted  $\text{PbI}_2$  phase fraction.

The  $E_{\text{cb}}$  of  $\text{PbI}_2$  is 0.26 eV higher than the  $E_{\text{cb}}$  of  $\text{TiO}_2$  and thus  $\text{PbI}_2$  satisfies the conditions of a charge-recombination/interception barrier layer.

In order to probe the hypothesis that  $\text{PbI}_2$  acts as a charge-interception barrier, dark current measurements, in which electrons flow from  $\text{TiO}_2$  to the HOMO of the HTM, were made. Consistent with our hypothesis, Figure 6 illustrates that the onset of the dark current occurs at lower potentials as the  $\text{PbI}_2$  concentration decreases. In the absence of other effects, the increasing dark current with increasing fraction of perovskite (and decreasing fraction of  $\text{PbI}_2$ ) should result in progressively lower open-circuit photovoltages. Instead, the photocurrent density and the open-circuit photovoltage both increase, at least until to  $\text{PbI}_2$  fraction reaches 1.7%. As discussed above, thinning of a  $\text{PbI}_2$ -based

FIG. 7. Cross-sectional SEM images of  $\text{CH}_3\text{NH}_3\text{PbI}_3$  film with different dipping time.

sandwich layer should lead to higher net injection yields, but excessive thinning would diminish the effectiveness of  $\text{PbI}_2$  as a barrier layer for back electron transfer reactions.

Given the surprising role of remnant  $\text{PbI}_2$  in these devices, we further probed the two-step conversion process by using scanning-electron microscopy (SEM) (Figure 7). Two domains of lead-containing materials ( $\text{PbI}_2$  and  $\text{MAPbI}_3$ ) are present. The first domain is sited within the mesoporous  $\text{TiO}_2$  network (area 1) while the second grows on top of the network (area 2). Area 2 initially contains 200 nm crystals. As the dipping time is increased, the crystals show marked changes in size and morphology. The formation of bigger perovskite crystals is likely the result of the thermodynamically driven Ostwald ripening process, i.e., smaller perovskite crystals dissolves and re-deposits onto larger perovskite crystals.<sup>22</sup> The rate of charge-interception, as measured via dark current, is proportional to the contact area between the perovskite and the HTM. Thus, the eventual formation of large, high-aspect-ratio crystals, as shown in Figure 7, may well lead to increases in contact area and thereby contributes to the dark-current in Figure 6. Regardless, we found that the formation of large perovskite crystals greatly decreased our success rate in constructing high-functioning, non-short-circuiting solar cells.

In summary, residual  $\text{PbI}_2$  appears to play an important role in boosting overall efficiencies for  $\text{CH}_3\text{NH}_3\text{PbI}_3$ -containing photovoltaics.  $\text{PbI}_2$ 's role appears to be that of a  $\text{TiO}_2$ -supported blocking layer, thereby slowing rates of electron( $\text{TiO}_2$ )/hole(perovskite) recombination, as well as decreasing rates of electron interception by the hole-transporting material. Optimal performance for energy conversion is observed when ca. 98% of the initially present  $\text{PbI}_2$  has been converted to the perovskite. Conversion to this extent requires about 15 min. Pushing beyond 98% (and beyond 15 min of reaction time) diminishes cell performance and diminishes the success rate in constructing non-short-circuiting cells. The latter problem is evidently a consequence of conversion of small and more-or-less uniformly packed perovskite crystallites to larger, poorly packed crystallites of varying shape and size. Finally, the essential, but previously unrecognized, role played by remnant  $\text{PbI}_2$  provides an additional explanation for why cells prepared dissolving and then depositing pre-formed  $\text{CH}_3\text{NH}_3\text{PbI}_3$  generally under-perform those prepared via the intermediacy of  $\text{PbI}_2$ .

We thank Prof. Tobin Marks for use of the solar simulator and EQE measurement system. Electron microscopy was done at the Electron Probe Instrumentation Center (EPIC) at Northwestern University. Ultraviolet Photoemission Spectroscopy was done at the Keck Interdisciplinary Surface Science facility (Keck-II) at Northwestern University. This research was supported as part of the
